ABSTRACT

Perivascular epithelioid cell tumors (PEComa) are a rare type of mesenchymal tumor arising from perivascular epithelial cells. These tumor cells are a co-expression of both melanocytic and myogenic antigens, such as HMB 45 and smooth muscle actin, and at least in some patients, are located around vessels. PEComas has been reported at various sites, including visceral organs, soft tissue, the prostate gland and broad ligaments. In the female reproductive system, the uterine corpus is the most common site of involvement. Some cases are related to tuberous sclerosis complex. Cervical PEComa with tuberous sclerosis complex is presented in the case of a 41 year-old and the literature is reviewed. There have been only eight cases of cervical PEComas and only one other case associated with tuberous sclerosis complex reported to date.

Key Words: Perivascular epithelioid cell neoplasm, Uterine cervical neoplasm, Tuberous sclerosis

INTRODUCTION

The perivascular epithelioid cell (PEC) was first reported in 1943 by Apitz. It was described in renal angiomyolipoma and considered an “abnormal myoblast”. In 1992, Bonetti et al. suggested the term “perivascular epithelioid” to define these cells (1). In 2002, the World Health Organization (WHO) designated PEComas as “mesenchymal tumors composed of histologically and immunohistochemically distinctive perivascular epithelioid cells” (2). It is a recognized as group of tumors containing PEC differentiation and includes renal or extra renal angiomyolipoma (AML), lymphangioleiomyomatosis (LAM), clear cell “sugar” tumor (CCST) of the lung, clear-cell myomelanocytic tumor of the falciform ligament, and a heterogeneous group of rare, clear cell tumors in other locations (2).

PEComa is a generally acknowledged as a family of tumors but there are also some uncertainties about their designation. Their differential diagnosis has been problematic and the association with epithelioid smooth muscle tumor is debatable. Because of the limited number of cases reported, the biological behavior of uterine PEComas is also uncertain, especially those of the cervix (3). Although most uterine PEComas are benign or have uncertain malignancy potential, malignant PEComas have been reported, although rarely (4). Only eight cases of PEComa in the cervix and one other case associated with tuberous sclerosis complex (TSC) have been reported. We present the clinical and histopathological features of a cervical PEComa case and emphasize differential diagnosis and regular monitoring.

CASE REPORT

A 41-year-old virgin woman was admitted to hospital with a history of intermittent vaginal bleeding for fifteen days. She had a remarkable history of TSC, with epileptic seizures starting at the age of two, intellectual disability, radiological evidence of angiomyolipomas in the liver and kidney parenchyma, and cutaneous hypopigmented macula. She was taking antiepileptic drugs for seizures. Transabdominal sonography suggested a complex cervical mass. Magnetic resonance imaging confirmed a 4 x 3.5 cm solid, cervical mass originating from the right, lateral wall of the cervix.

On the evening of hospitalization, she had excessive vaginal bleeding which necessitated emergency surgery. The intraoperative findings from the abdominal cavity and ovaries were normal. However, there was a solid cervical mass of approximately 4 x 3 cm in diameter.

Pathological Findings

Macroscopically, the uterus measured 9 x 5x 3.5 cm and there was a friable, solid mass arising from the cervix. The mass was measured at 4 x3.5x2 cm. The section of the mass was gray-white in color and had areas of hemorrhage.
Microscopically, the cervical mass had a small, infiltrative growth pattern (Figure 1). It consisted of a fascicular and sheet-like pattern of epithelioid cells that had well defined margins. Cellularity was moderate and there was a scant amount of intervening stroma which was rich in blood vessels. Areas of hemorrhage and focal necrosis constituted less than 5% of the tumor. Tumor cells were of medium size, round to polygonal in shape, eosinophilic, and had pale granular cytoplasm with round nuclei (Figure 2). There were some multinucleated cells and ‘spider like’ giant cells (Figure 3A,B), but they were rare. The mitotic count was 1 per 50 under high power field (HPF) and none of them was atypical. Lymphovascular invasion was not detected. Immunohistochemically, these cells were diffusely positive for HMB45 (dilution 1:100, clone HMB45, Thermo Scientific), vimentin (dilution 1:100, clone SP20, Thermo Scientific), desmin (dilution 1:150, clone D33, Thermo Scientific) and caldesmon (ready to use, clone h-CALD, Thermo Scientific), and focally positive for SMA (dilution 1:800, clone 1A4, Thermo Scientific) (Figure 4). The tumor cells were negative for cytokeratin (dilution 1:50, clone AE1/AE3, Thermo Scientific), CD-10 (dilution 1:50, clone 56C6, Thermo Scientific), S-100 (Ready to use, clone 4C4.9, Thermo Scientific), CD-68 (dilution 1:1000, clone KP-1, Thermo Scientific) and CD-34 (dilution 1:400, clone QBEnd/10, Novocastra). The Ki-67 (ready to use, clone SP6, Thermo Scientific) index was 3-4 %. The endometrium, myometrium and both ovaries were free of the tumor. The final histological diagnosis was PEComa arising from the cervix. Close surveillance of the patient for the following three years produced no evidence of recurrence or metastasis.

**DISCUSSION**

In 1991, it was reported that renal AML and CCST of the lung displayed HMB45 immunoreactivity, which is a marker for tumors displaying melanocytic differentiation (5). In addition to immunophenotypic similarities, both tumors share a distinctive cell type, with an epithelioid to spindle cell shape, a clear or eosinophilic granular cytoplasm, and a perivascular distribution (4). Bonetti et al. reported the same histopathologic and immunohistochemical findings in LAM of the lung. They suggested that CCST, AML and LAM are in the same group of tumors because they originate from the same cell type, which is the “perivascular epithelioid cell”(6).

The normal counterpart and origin of PEC is unknown. It has been hypothesised that these cells originate from melanocytic cells, smooth muscle cells, pericytic cells or perivascular cells, or originate from undifferentiated cells of the neural crest that are positive with both melanocytic and myogenic antigens (1). Fukunaga proposed that primitive mesenchymal cells could be differentiating towards both smooth muscle and HMB45 positive PEC and that the degree of differentiation may differ between cases. Therefore, some tumors may show pure PEC or pure smooth muscle differentiation, and some of them may show incomplete differentiation (3).

Until the last few years, uterine epithelioid mesenchymal tumors were thought to be epithelioid smooth muscle tumors. Recently, it was reported that uterine epithelioid tumors were comprised focally or entirely of HMB45 positive cells. These cells have a histopathological and

PEComa is a distinct entity, if the tumor is related to TSC and LAM, the occurrence of multinucleated giant cells and ‘spider like’ cells are indicative of PEComa under the current concept. A delicate capillary network and cytokeratin negativity also indicate of PEComa (9).

Eight cases of cervical PEComa have been reported (4, 10-15). Clinical findings, treatment and follow-up of these cases are presented in Table I. In the present case, the patient was treated with total hysterectomy and bilateral salpingo-oopherectomy and through three years of checkups there was no recurrence.

PEComas are related to TSC, which is a genetic disorder attributable to the absence of the TSC1 (9q34) or TSC2 (16p13.3) genes. Clinically, it is characterized by mental retardation, seizures, intellectual disability and some tumors, such as cardiac rhabdomyomas, AMLs, subependymal giant cell tumors, cutaneous angiofibromas and LAM. Similar absences of the TSC genes are indicated in some PEComas when related to TSC, and in sporadic cases (1). According to the reported cases, the presence of PEComa with the tuberous sclerosis complex varies between 6-9% (11,14). Schoolmeester et al. investigated the clinical and pathological features of 16 gynecological PEComa cases, and 1 had a history of TSC (16). In the present study, the cervical PEComa was also associated with TSC and therefore represents the second cervical PEComa case associated with TSC.

Owing to the rarity of PEComas, it is not yet possible to produce a prognostic classification and to predict the biological behavior of these tumors. Folpe et al. reported 26 cases of PEComa in soft tissue and the female reproductive
tract. Of these patients, 24 were followed up (mean 30 months) and metastasis was detected in 8 patients. Folpe et al. proposed criteria to classify these tumors as 'benign', 'uncertain malignancy potential' and 'malignant'. In the same research, they reported a meaningful relationship between tumor size (>5 cm), mitotic activities (>1/50 HPF), necrosis, high nuclear grade and infiltrative growth pattern with aggressive behavior (14). Schoolmeester et al. investigated the clinical and pathological features of 16 gynecological PEComa cases (mean follow-up 26 months) and they suggested a modified classification system; namely, if there are 4 or more unfavorable histological findings (size ≥5 cm, mitosis ≥1/50 HPF, significant nuclear atypia, necrosis, lymphovascular invasion), the tumor is classified as malignant. If none of criteria are met, the tumor is classified as benign. If the tumor meets 1 to 3 of the criteria, it is difficult to predict the behavior of the tumor. Therefore, it is classified as 'benign or of uncertain malignancy potential' (16). According to the modified system, our case had one unfavorable feature (focal necrosis) for aggressive behavior. However, there was no evidence of recurrence or metastasis after three years of regular checkups.

In summary, this case is reported to increase awareness among pathologists of the need for inclusion of PEComa in the differential diagnosis of epithelioid uterine mesenchymal tumors because their histopathological criteria for predicted biological behavior and classification are different from epithelioid smooth muscle tumors. Given the small series of reported cases, the most effective

*TSC: Tuberous Sclerosis Complex*
treatment approach for uterine PEComa is also uncertain. Large numbers of cases with long duration follow-up of their clinical behavior are required to confirm the effective management and prognostic classification of this tumor. Based on limited current data, uterine and cervical PEComas should be considered tumors of uncertain malignancy potential. They should be monitored for a long period because of their potential for local recurrence and metastasis. At least some of these tumors, as in our case, have a close relationship with TSC. It is therefore important to recognize PEComa in the evaluation and diagnosis of the other components of TSC.
